Abstract: The Karplus relations for vicinal J couplings, which relate the peptide backbone angles $\phi$ and $\psi$ to $^{3}J(H^{\alpha}-N)$ and $^{3}J(H^{N}-C')$, have been reparametrized on the basis of measurements made on uniformly $^{13}C/^{15}N$-enriched human ubiquitin and backbone angles derived from the 1.8 Å X-ray structure of this protein (Vijay-Kumar, S.; Bugg, C. E.; Cook, W. J. J. Mol. Biol. 1987, 194, 531–544). For $^{3}J(H^{\alpha}-N)$, values measured using an E.COSY-type HCACO experiment fall in the -1.9 to 0.1 Hz range and are described by the following: $^{3}J(H^{\alpha}-N) = -0.88 \cos^2(\psi + 60^\circ) - 0.61 \cos(\psi + 60^\circ) - 0.27$. The root-mean-square difference (rmsd) between measured values and the Karplus relation is 0.16 Hz. Values measured for $^{3}J(H^{N}-C')$ using an E.COSY-type HNCA experiment fall in the -0.4 to 3.6 Hz range, are described by 4.0 $\cos^3(\phi) + 1.1 \cos(\phi) + 0.1$, and fit the observed J couplings with an rmsd of 0.45 Hz.

The importance of three-bond J couplings for determining three-dimensional molecular conformation by NMR methods is well-established. For peptides and proteins a wide variety of different J couplings is readily accessible and is commonly being used in the structure determination process. For most common types of three-bond J couplings the Karplus equation,1 which correlates J with the intervening torsion angle, has been parametrized on the basis of conformationally constrained small molecules with similar patterns of substituents as the molecule of interest.2 A more direct approach was used by Pardi et al.,3 who parametrized the Karplus relation for $^{3}J(H^{N}-H^{\alpha})$ by relating the J values measured for peptide amides in pancreatic trypsin inhibitor to the dihedral angles available from high-resolution crystallographic studies. Very similar values for the Karplus coefficients describing $^{3}J(H^{N}-H^{\alpha})$ were also derived using a range of other proteins.4,5 The present paper describes use of the same approach to parametrize Karplus equations for $^{3}J(H^{N}-C')$ and $^{3}J(H^{\alpha}-N)$, which are related to the peptide backbone angles $\phi$ and $\psi$, respectively. Our study uses a sample of human ubiquitin, a protein which commercially can be obtained uniformly enriched with $^{13}C$ and $^{15}N$ (VLI Research, Southeastern, PA) and for which a high-resolution crystal structure is available.6

In peptides and proteins the most common ways to measure heteronuclear J couplings are E.COSY-based techniques7 and quantitative J correlation,8 a method in which the strength of a long-range correlation is related in a simple manner to the intensity of the corresponding cross peak. For measurement of J couplings that are more than an order of magnitude smaller than the transverse relaxation rate of the observed nucleus, the E.COSY technique generally yields better results. E.COSY-based techniques require three magnetically active nuclei, say $^{1}H^{a}$, $^{13}C'$, and $^{15}N$. If the spin state of the $^{15}N$ is left unperturbed during an experiment in which $^{1}H^{a}$ is correlated with $^{13}C'$ (in, for example, an HCACO experiment6), two cross peaks are obtained for each $^{1}H^{a}-^{13}C'$ correlation, corresponding to $^{15}N$ in the (a) and (b) spin states. The displacement in the $^{13}C'$ dimension then corresponds to $^{3}J(C'-N)$, whereas that in the $^{1}H^{a}$ dimension is $^{3}J(H^{a}-N)$. Provided the $^{3}J(C'-N)$ splitting is resolved, the much smaller $^{3}J(H^{a}-N)$ is easily measured. Any change in $^{15}N$ spin state between the evolution of $^{13}C'$ magnetization and the end of $^{1}H^{a}$ detection will result in a reduction of the apparent $^{3}J(H^{a}-N)$ splitting,10,11 and it is therefore important that the passive nucleus ($^{15}N$) has a $T_1$ relaxation time which is long compared to the duration of the experiment. By conducting the HCACO experiment in $D_2O$, the backbone $^{15}N$ atoms are deuterated and have desirably long $T_1$ values of nearly 1 s. An alternative HN(C0)CA E.COSY type technique12 requires that the spin state of $^{15}N$ remains unchanged. However, as $^{1}H^{a}$ changes its spin state rapidly due to homonuclear NOE effects, use of a deuterated $^{15}N$ as a passive spin is preferred over that of $^{1}H^{a}$. For measurement of $^{3}J(H^{N}-C')$, a HNCA E.COSY type experiment12,13 in which the carbonyl spin state remains unperturbed has been used. As the $^{13}C'$ spin relaxation is not dominated by a large one-bond $^{13}C'-^{1}H$ interaction, its longitudinal relaxation time is relatively long (~1 s) and $^{13}C'$ $T_1$ relaxation therefore has minimal effect on the measured J coupling. To avoid confusion with a related HNCA E.COSY-based technique for measurement of $^{3}J(H^{N}-H^{a})$ J couplings,14 we include the passive...
Reparametrization of the Karplus Relation for J Couplings

spin to which the J coupling is measured between square brackets in the name of the pulse sequence. The schemes used in the present study will therefore be referred to as HCACO-N-E.COSY and HNCA[CO]-E.COSY.

Experimental Section

Two separate samples of uniformly [13C/15N] enriched human ubiquitin (8.5 kDa) were used, 3.5 mg each in 220 µL Shigemi microcells (Shigemi Inc., Allison Park, PA) containing 30 mM sodium acetate buffer, pH 4.7. A D₂O sample was used for the HCACO-N-E.COSY experiment and a H₂O sample for HNCA[CO]-E.COSY. All data were recorded at 30 °C on a Bruker AMX-600 spectrometer, equipped with a triple resonance pulsed field gradient probehead. The HCACO-N-E.COSY pulse sequence (Figure 1A) used in the present study differs from a previously described HCACO experiment by the omission of 15N decoupling and pulsing and by additional pulsed field gradients. A 26 x 156 x 384 3D data matrix was acquired with acquisition times of 6.9 (t₁), 86.1 (t₂), and 127 ms (t₃). Data were zero filled to yield a digital resolution of 30 (F₁), 1.8 (F₂), and 0.74 Hz (F₃).

The HNCA(CO)-E.COSY pulse sequence (Figure 1B) is very similar to a scheme described by Weisemann et al., except for the omission of shaped pulse C5 decoupling during H2O data acquisition (because of hardware malfunctioning at the time the data were recorded) and a slightly different approach to suppression of the H2O resonance. The sequence yields distortion free spectra—a critical prerequisite for reliable J coupling measurement—but there is no indication that results of similar quality could not be obtained with the various sequences proposed by Weisemann et al. A 264 × 1024 × 512 3D data matrix was acquired with acquisition times of 22 ms (t1), 28 ms (t2), and 65 ms (t3). Data were zero filled to yield a digital resolution of 9.3 (F1), 3.5 (F2), and 1.9 Hz (F3). Peak positions were determined using the program CAPP.

Results and Discussion

The HNCA(CO)-E.COSY experiment was carried out as both a 7-h 2D (without C5 chemical shift evolution) and a 45 h 3D experiment. A small region of the 2D HNCA(CO)-E.COSY is shown in Figure 2. Fifty nine J couplings could be extracted from the 2D spectrum, and 67 values from the 3D. For the 59 J couplings for which two measurements are available, the pairwise rms difference is 0.16 Hz, indicating that the random error in their averaged value is 0.08 Hz. Measured 3J(Hα-N) values all fall in the -1.9 to 0.1 Hz range (supplementary material). Using singular value decomposition, coefficients A, B, and C are derived which give the best fit to the Karplus equation: 3J(Hα-N) = A cos2(ψ + 60°) + B cos(ψ + 60°) + C. The uncertainty in the coefficients is assessed by repeating the procedure 10 000 times, each time randomly omitting 10% of the measured data, resulting in A = -0.88 ± 0.03, B = -0.61 ± 0.01, C = -0.27 ± 0.03. This Karplus curve, the measured data points, and the total range of Karplus curves obtained from the 10 000 fits are shown in Figure 3A. The present parametrization of the 3J(Hα-N) Karplus curve is strikingly different from the original one, which was based on theoretical calculations and which predicted 3J(Hα-N) values in the +1.1 to -6.6 Hz range. Kopple et al. and Barfield had pointed out previously that the original Karplus parametrization of this coupling provides poor results and that the drastic change we find for A, B, and C therefore is not surprising. However, considering that the rms deviation of the measured data points (excluding couplings to Pro 15N) from the Karplus curve (0.16 Hz) is approximately 10 times smaller than the range of J couplings, 3J(Hα-N) provides at least as good a measure for ψ as any other J coupling for other dihedral angles, despite its small magnitude. Unfortunately, in the 50° < ψ < 180° range 3J(Hα-N) depends only weakly on ψ and therefore this coupling does not provide a good indicator for the value of ψ in regions of extended structure. In contrast to previous suggestions, it is possible to relate ψ to 3J(Hα-N) without considering the other backbone angles ϕ and θ. Based on comparison of the 3J(Hα-N) values measured in ubiquitin with those previously measured in small model compounds, it appears that 3J(Hα-N) is sensitive to substituent effects. 3J(Hα-N) values measured to the 15N of the three prolines in ubiquitin appear to confirm this notion, as the 3J(Hα-N) couplings to all three proline nitrogens (non-protonated) fall more than two standard deviations above the Karplus parametrization.

Reparametrization of the Karplus Relation for J Couplings

Sixty $^3J(H^N-C')$ couplings, obtained from the 3D HNCA(CO)-E.COSY measurement, fall in the -0.4 to 3.6 Hz range. The rms difference between the values measured from a 22 h 2D version of the experiment (without $^{15}N$ evolution) and the 3D experiment is 0.17 Hz, suggesting that the rms error in the 3D-derived $^3J(H^N-C')$ values is ca. 0.1 Hz. Optimal parametrization of the Karplus curve, $^3J(H^N-C') = A \cos^2(\phi) + B \cos(\phi) + C$, in the same manner as described above, yields $A = 4.01 \pm 0.14$, $B = 1.09 \pm 0.06$, and $C = 0.07 \pm 0.02$. The rms difference between measured $J$ splittings and values predicted on the basis of this curve (Figure 3B) is 0.45 Hz. Although the original $A$, $B$, and $C$ Karplus parameters (5.8, -2.7, 0.1) fall well outside the standard error of our new parametrization, use of the older curve (dashed line in Figure 3B) does not invalidate previous work based on qualitative interpretation of $^3J(H^N-C')$.

A protein of known structure provides an ideal "model compound" for parametrization of Karplus equations for all types of couplings that are of interest for protein structure determination by NMR. The deviation between measured $J$ values and those predicted from the 1.8 Å X-ray structure of human ubiquitin does not show a significant increase in regions where the Karplus equation has its steepest angular dependence, suggesting that for ubiquitin the uncertainty in the crystallographically determined backbone angles is not limiting the accuracy at which the Karplus parameters can be determined.
